The piranha problem: Large effects swimming in a small pond

Christopher Tosh, Philip Greengard, Ben Goodrich, Andrew Gelman, Aki Vehtari, and Daniel Hsu

1 Background

In this work, we discuss an inevitable consequence of having a stable system in which many explanatory variables have large effects: these variables must have large interactions which will be unlikely to cancel either out to the extent required for general stability or predictability. We call this type of result a “piranha theorem” (Gelman, 2017), the analogy being the folk wisdom that if one has a large number of piranhas (representing large effects) in a single fish tank, then one will soon be left with far fewer piranhas. If there is some outcome for which a large number of studies demonstrate effects of novel explanatory variables, then we can conclude that some of these effects are smaller than claimed or that multiple explanatory variables are essentially measuring the same phenomenon.

Identifying and measuring the effects of explanatory variables are central problems in statistics and drive much of the world’s scientific research. Despite the substantial effort spent on these tasks, there has been comparatively little work on addressing a related question: how many explanatory variables can have large effects on an outcome? The present work follows up on Cornfield et al. (1959) and Ding and Vanderweele (2014), considering quantitative constraints in the effects of additional variables.

Consider, for example, the problem of explaining voters’ behaviors and choices. Researchers have identified and tested the effects of internal factors such as fear, hope, pride, anger, anxiety, depression, and menstrual cycles, as well as external factors such as droughts, shark attacks, and the performance of local college football teams. Many of these findings have been questioned on methodological grounds, but they remain in the public discourse. Beyond the details of these particular studies, it is natural to ask if all of these effects can be real in the sense of representing patterns that will consistently appear in the future.

The implication of the published and well-publicized claims regarding ovulation and voting, shark attacks and voting, college football and voting, etc., is not merely that some voters are superficial and fickle. No, these papers claim that seemingly trivial or irrelevant factors have large and consistent effects, and this runs into the problem of interactions. For example, the effect on your vote of the local college football team losing could depend crucially on whether there’s been a shark attack lately, or on what’s up with your hormones on election day. Or the effect could be positive in an election with a female candidate and negative in an election with a male candidate. Or the effect could interact with your parents’ socioeconomic status, or whether your child is a boy or a girl, or the latest campaign ad, or any of the many other factors that have been studied in the evolutionary psychology and political psychology literatures. If such effects are large, it is necessary to consider their interactions, because the average effect of a factor in any particular study will depend on the levels of all the other factors in that environment. Similarly, Mellon (2020) has argued against naive assumptions of causal identification in economics, where there is a large literature considering rainfall as an instrumental variable, without accounting for the implication that these many hypothesized causal pathways would, if taken seriously, represent violations of the assumption of exclusion restriction.

These concerns are particularly relevant in social science, where the search for potential causes is open-ended. Our work here is partly motivated by the replication crisis, which refers to the difficulties that many have had in trying to independently verify established findings in social and biological sciences. Many of the explanations for the crisis have focused on various methodological issues, such as low power and unrecognized

researcher degrees of freedom (Simmons et al., 2011). Beyond the criticisms of practice and suggested fixes, these works have also provided much needed statistical intuition. Groups of studies that claim to have found a variety of important explanatory variables for a single outcome should be scrutinized, particularly when the dependencies among the explanatory variables have not been investigated.

This article collects several mathematical results regarding the distributions of correlations or coefficients, with the aim of fostering further work on statistical models for environments with a multiplicity of effects. What is novel in this paper is not the theorems themselves but rather viewing them in the context of trying to make sense of clusters of research studies that claim to have found large effects.

There are many ways to capture the dependence among random variables, and thus we should expect there to be a correspondingly large collection of piranha theorems. We formalize and prove piranha theorems for correlation, regression, and mutual information in Section 4. These theorems illustrate the general phenomena at work in any setting with multiple causal or explanatory variables, with implications for the replication crisis in social science.

2 Piranhas and butterflies

A fundamental tenet of social psychology and behavioral economics, at least how it is presented in the news media, and taught and practiced in many business schools, is that small “nudges,” often the sorts of things that we might not think would affect us at all, can have big effects on behavior.

The model of the world underlying these claims is not just the “butterfly effect” that small changes can have big effects; rather, it’s that small changes can have big and predictable effects, a sort of “button-pushing” model of social science, the idea that if you do \( A \), you can expect to see \( B \).

In response to this attitude, we present the piranha argument, which states that there can be some large and predictable effects on behavior, but not a lot, because, if there were, then these different effects would interfere with each other, a “hall of mirrors” of interactions (Cronbach, 1975) that would make it hard to detect any consistent effects of anything in observational data.

In a similar vein, Cook (2018) writes:

“The butterfly effect is the semi-serious claim that a butterfly flapping its wings can cause a tornado half way around the world. It’s a poetic way of saying that some systems show sensitive dependence on initial conditions, that the slightest change now can make an enormous difference later . . . Once you think about these things for a while, you start to see nonlinearity and potential butterfly effects everywhere. There are tipping points everywhere waiting to be tipped!”

But, Cook continues, it’s not so simple:

“A butterfly flapping its wings usually has no effect, even in sensitive or chaotic systems. You might even say especially in sensitive or chaotic systems. Sensitive systems are not always and everywhere sensitive to everything. They are sensitive in particular ways under particular circumstances and can otherwise be resistant to influence. . . . The lesson that many people draw from their first exposure to complex systems is that there are high-leverage points, if only you can find them and manipulate them. They want to insert a butterfly to at just the right time and place to bring about a desired outcome. Instead, we should humbly evaluate to what extent it is possible to steer complex systems at all. We should evaluate what aspects can be steered and how well they can be steered. The most effective intervention may not come from tweaking the inputs but from changing the structure of the system.”

Whether thinking in terms of butterflies or piranhas, we can think of an infinite series of potential effects, which implies that only a few can be large and also creates the possibility of interactions that, after some point, overwhelm any main effects.

3 Example: hypothesized effect sizes in social priming

We demonstrate the possibility of quantitative analysis of the piranha problem using the example of an influential experiment from 1996 in which participants were given a scrambled-sentence task and then were surreptitiously timed when walking away from the lab (Bargh et al., 1996). Students whose sentences
included elderly-related words such as “worried,” “Florida,” “old,” and “lonely” walked an average of 13% more slowly than students in the control condition, and the difference was statistically significant.

This experimental claim is of historical interest in psychology in that, despite its implausibility, it was taken seriously for many years and received thousands of citations, but it failed to replicate and is no longer generally believed to represent a real effect; for background see Wagenmakers et al. (2015). Now we understand such apparently statistically-significant findings as the result of selection with many researcher degrees of freedom (Simmons et al., 2011). Here, though, we will take the published claim at face value and also work within its larger theoretical structure, under which weak indirect stimuli can produce large effects.

An effect of 13% on walking speed is not in itself huge; the difficulty comes when considering elderly-related words as just one of many potential stimuli. Here are just some of the factors that have been published in the social priming and related literatures as having large effects on attitudes and behavior: hormones, subliminal images, news of football games and shark attacks, a chance encounter with a stranger, parental socioeconomic status, weather, the last digit of one’s age, the sex of a hurricane name, the sexes of siblings, the position in which a person is sitting, and many others. See Gelman (2023) for references to these claims, along with other papers criticizing or refuting them. A common feature of these examples is that the stimuli have no clear direct effect on the measured outcomes, and in many cases the experimental subject is not even aware of the manipulation. Based on these examples, one can come up with dozens of other potential stimuli that fit the pattern. For example, in addition to walking speed being affected by elderly-related words, one could also consider word lengths (with longer words corresponding to slower movement), sounds of words (with smooth sibilance motivating faster walking), subject matter (sports-related words as compared to sedentary words), affect (happy compared to sad words, or calm compared to angry), words related to travel (inducing faster walking) or invoking adhesives such as tape or glue (inducing slower walking), and so on. Similarly, one can consider many different sorts of incidental events, not just encounters with strangers but also a ringing phone or knocking at the door, the presence of a male or female lab assistant (which could have a main effect or interact with the participant’s sex), the presence or absence of a newspaper or magazine on a nearby table, ad infinitum.

Now we can invoke the piranha principle. Imagine 100 possible stimuli, each with an effect of 13% on walking speed, all of which could arise in a real-world setting where we encounter many sources of text, news, and internal and external stimuli. If the effects are independent, then at any given time we could expect, on the log scale, a total effect with standard deviation \(0.5\sqrt{100\log(1.13)} = 0.61\), thus walking speed could easily be multiplied or divided by \(e^{0.61} = 1.8\) based on a collection of arbitrary stimuli that are imperceptible to the person being affected. And this factor of 1.8 could be made arbitrarily large by simply increasing the number of potential primes.

It is outrageous to think that walking speed could be doubled or halved based on a random collection of unnoticed and essentially irrelevant stimuli—but that is the implication of the embodied cognition literature. It is basically a Brownian motion model in which the individual inputs are too large to work out.

We can think of four ways to avoid the ridiculous conclusion. The first possibility is that the different factors could interact or interfere in some way so that the variance of the total effect is less than the sum of the variances of the individual components. Second, effects could be much smaller. Change those 13% effects to 1% effects and you can get to more plausible totals, in the same way that real-world Brownian oscillations are tolerable because the impact of each individual molecule in the liquid is so small. Third, one could reduce the total number of possible influences. If there were only 10 possible stimuli rather than 100 or 1000 or more, then the total effect could fall within the range of plausibility. Fourth, there could be a distribution of effects with a few large effects and a long tail of relatively unimportant factors, so that the infinite sum has a reasonable bound.

All four of these options have major implications for the study of social priming and, more generally, for causal inference in an open-ended setting with large numbers of potential influences. First, if large interactions are possible, this suggests that stable individual treatment effects might be impossible to find: a 13% effect of a particular intervention in one particular experiment might be −18% in another context or +2% in the presence of some other unnoticed factor, and this in turn raises questions about the relevance of any particular study. Second, if effects are much smaller than reported, this suggests that existing studies are
Thus, \( E \) Define Proof. Without loss of generality, we may assume that \(|z_i| \leq \tau \). In particular, if \( |z_i| \geq \tau \) for each \( i = 1, \ldots, p \), then \( \sum_{i \neq j} |\text{corr}(X_i, X_j)| \geq p(\tau^2 p - 1) \).

Proof. Without loss of generality, we may assume that \( X_1, \ldots, X_p, y \) have mean zero and unit variance. Define \( Z_1, \ldots, Z_p \) by

\[
Z_i = \begin{cases} 
  X_i & \text{if } E(yX_i) > 0, \\
  -X_i & \text{else}.
\end{cases}
\]

Thus \( E(yZ_i) = |E(yX_i)| \) and \( E(Z_i^2) = E(X_i^2) \) for each \( i = 1, \ldots, p \). By Cauchy-Schwarz,

\[
\sum_{i=1}^{p} E(yZ_i) = E\left(y \sum_{i=1}^{p} Z_i \right) \leq \sqrt{E\left( \sum_{i=1}^{p} Z_i^2 \right)}.
\]

Therefore,

\[
\sum_{i=1}^{p} |E(yX_i)| = \sum_{i=1}^{p} E(yZ_i) \leq \sqrt{\sum_{i=1}^{p} E(Z_i^2) + \sum_{i \neq j} E(Z_iZ_j)} \leq \left( \sum_{i=1}^{p} E(Z_i^2) + \sum_{i \neq j} E(Z_iZ_j) \right)^{1/2}.
\]

Rearranging gives us the theorem statement.

A direct consequence of Theorem 1 is that if \( X_1, \ldots, X_p \) are independent (or uncorrelated) random variables and each has correlation at least \( \tau \) with \( y \), then \( \tau \leq 1/\sqrt{p} \).

In some situations, the outcome may change from study to study, for example a program evaluation in economics might look at employment, income, or savings; a political intervention might target turnout or vote choice; or an education experiment might look at several tests. Although the different outcomes in a

4 Piranha theorems

In this section, we present piranha theorems for linear and nonlinear effects. We consider two different ways of measuring linear effects. First, we show that it is impossible for a large number of explanatory variables to be correlated with some outcome variable unless they are highly correlated with each other. Second, we show that if a set of explanatory random variables is plugged into a linear regression, the \( \ell_2 \)-norm \( \| \beta \| \) of the least-squares coefficient vector \( \beta \) can be bounded above in terms of the eigenvalues of the second-moment matrix of the predictors. Thus, there can only be so many individual coefficients with a large magnitude. Finally, we consider a general nonlinear form of dependency, mutual information, and present a corresponding piranha theorem for that measure.

4.1 Correlation

The first type of pattern we consider is correlation. In particular, we will show that if all the covariates are highly correlated with some outcome variable, then there must be a reasonable amount of correlation among the covariates themselves. This is formalized in the following theorem, which is known as Van der Corput’s inequality (Tao, 2014). We offer a proof here for completeness.

**Theorem 1** (Van der Corput’s inequality). If \( X_1, \ldots, X_p, y \) are real-valued random variables with finite nonzero variance, then

\[
\sum_{i=1}^{p} |\text{corr}(X_i, y)| \leq \sqrt{p + \sum_{i \neq j} |\text{corr}(X_i, X_j)|}.
\]

In particular, if \( |\text{corr}(X_i, y)| \geq \tau \) for each \( i = 1, \ldots, p \), then \( \sum_{i \neq j} |\text{corr}(X_i, X_j)| \geq p(\tau^2 p - 1) \).

Proof. Without loss of generality, we may assume that \( X_1, \ldots, X_p, y \) have mean zero and unit variance. Define \( Z_1, \ldots, Z_p \) by

\[
Z_i = \begin{cases} 
  X_i & \text{if } E(yX_i) > 0, \\
  -X_i & \text{else}.
\end{cases}
\]

Thus \( E(yZ_i) = |E(yX_i)| \) and \( E(Z_i^2) = E(X_i^2) \) for each \( i = 1, \ldots, p \). By Cauchy-Schwarz,

\[
\sum_{i=1}^{p} E(yZ_i) = E\left(y \sum_{i=1}^{p} Z_i \right) \leq \sqrt{E\left( \sum_{i=1}^{p} Z_i^2 \right)}.
\]

Therefore,

\[
\sum_{i=1}^{p} |E(yX_i)| = \sum_{i=1}^{p} E(yZ_i) \leq \sqrt{\sum_{i=1}^{p} E(Z_i^2) + \sum_{i \neq j} E(Z_iZ_j)} \leq \sqrt{p + \sum_{i \neq j} |E(X_iX_j)|}.
\]

Rearranging gives us the theorem statement. □

A direct consequence of Theorem 1 is that if \( X_1, \ldots, X_p \) are independent (or uncorrelated) random variables and each has correlation at least \( \tau \) with \( y \), then \( \tau \leq 1/\sqrt{p} \).

In some situations, the outcome may change from study to study, for example a program evaluation in economics might look at employment, income, or savings; a political intervention might target turnout or vote choice; or an education experiment might look at several tests. Although the different outcomes in a
study are not exactly the same, we might reasonably expect them to be highly correlated. However, if we have mean-zero and unit-variance random variables \(x, y, z\) satisfying \(\mathbb{E}(xy) \geq \tau\) and \(\mathbb{E}(yz) \geq 1 - \epsilon\), then

\[
\mathbb{E}(xz) = \mathbb{E}(x(z - y + y)) \geq \tau + \mathbb{E}(x(z - y)),
\]

and, by Cauchy-Schwarz,

\[
\mathbb{E}(x(z - y))^2 \leq \mathbb{E}(x^2)\mathbb{E}((z - y)^2) \leq 2 - 2(1 - \epsilon).
\]

Thus, \(\mathbb{E}(xz) \geq \tau - \sqrt{2\epsilon}\). This gives the following corollary of Theorem 1.

**Corollary 2.** Suppose \(X_1, Y_1, \ldots, X_p, Y_p\) are real-valued random variables with finite nonzero variance. If

\[
\text{corr}(Y_i, Y_j) \geq 1 - \epsilon \quad \text{and} \quad |\text{corr}(X_i, Y_j)| \geq \tau \quad \text{for} \ i, j = 1, \ldots, p,
\]

then \(\sum_{i \neq j} |\text{corr}(X_i, X_j)| \geq p((\tau - \sqrt{2\epsilon})^2 - 1)\).

The bound in Theorem 1 is essentially tight for large \(p\). To see this, pick any \(0 \leq \tau \leq 1\) and take \(X_1, \ldots, X_p\) to be mean-zero random variables with covariance matrix \(\Sigma\) given by

\[
\Sigma_{ij} = \begin{cases} 
1 & \text{if } i = j, \\
\tau^2 & \text{if } i \neq j.
\end{cases}
\]

If \(y = \sum_{j=1}^p X_j\), then for each \(i = 1, \ldots, p\),

\[
\text{corr}(X_i, y) = \frac{\mathbb{E}(X_i \sum_{j=1}^p X_j)}{\sqrt{\mathbb{E}(\sum_{j,k=1}^p X_j X_k)}} = \frac{1 + (p - 1)\tau^2}{\sqrt{p + (p - 1)\tau^2}} \xrightarrow{p \to \infty} \tau.
\]

One drawback of Theorem 1 is that the upper bound depends on a coarse measure of interdependence of the covariates, namely the sum of all pairwise correlations \(\sum_{i,j} |\text{corr}(X_i, X_j)|\). One might hope that if we have a finer-grained control on the correlation matrix, we should be able to get a stronger result. This is accomplished by the following piranha theorem, which shows that we can instead get an upper bound that depends on the largest eigenvalue of the correlation matrix. However, this comes at the expense of bounding the sum of squared correlations \(|\text{corr}(X_i, Y_j)|^2\), rather than the sum of their absolute values.

**Theorem 3.** If \(X_1, \ldots, X_p, y\) are real-valued random variables with finite nonzero variance, then

\[
\sum_{i=1}^p |\text{corr}(X_i, y)|^2 \leq \lambda_{\max},
\]

where \(\lambda_{\max}\) is the maximum eigenvalue of the correlation matrix \(\Sigma_{ij} = \text{corr}(X_i, X_j)\).

Theorems 1 and 3 are generally incomparable since \(\sum_{i=1}^p |\text{corr}(X_i, y)|^2 \leq \sum_{i=1}^p |\text{corr}(X_i, y)|\), but

\[
\lambda^2_{\max} \leq \sum_{i,j} |\text{corr}(X_i, X_j)|^2 \leq \sum_{i,j} |\text{corr}(X_i, X_j)|.
\]

The proof of Theorem 3 relies on the following technical lemma, essentially a consequence of orthogonality.

**Lemma 4.** If \(U_1, \ldots, U_p, y\) are real-valued random variables with mean zero and unit variance such that \(\mathbb{E}(U_i U_j) = 0\) for all \(i \neq j\), then

\[
\sum_{i=1}^p (\mathbb{E}U_i y)^2 \leq 1.
\]

**Proof.** Denote the covariance matrix of the random vector \((U_1, \ldots, U_p, y)^T\) as

\[
\Sigma = \begin{pmatrix} I & a \\ a^T & 1 \end{pmatrix},
\]

where \(a_i = \mathbb{E}(U_i y)\) for \(i = 1, \ldots, p\). Define the vector \(v = (-a^T, \|a\|)^T \in \mathbb{R}^{p+1}\). Then

\[
v^T \Sigma v = 2(1 - \|a\|\|a\|) \geq 0,
\]

where the inequality follows from the fact that \(\Sigma\) is a covariance matrix and hence positive semi-definite. We conclude that \(\|a\| \leq 1\). \(\square\)
With the above in hand, we turn to the proof of Theorem 3.

**Proof of Theorem 3.** Assume without loss of generality that \( X_1, \ldots, X_p, y \) have mean zero and unit variance. Denote the eigendecomposition of \( \Sigma \) as \( Q \operatorname{diag}(\lambda_1, \ldots, \lambda_p)Q^T \), where \( \lambda_1 \geq \cdots \geq \lambda_p \geq 0 \) and \( Q \) is orthogonal.

Let \( \tilde{X} = Q^T X \), where \( X = (X_1, \ldots, X_p) \). Then \( \tilde{X} = (\tilde{X}_1, \ldots, \tilde{X}_p) \) is a mean-zero random vector whose covariance matrix is \( \operatorname{diag}(\lambda_1, \ldots, \lambda_p) \). For \( j \in \{1, \ldots, p\} \) with \( \lambda_j = \operatorname{var}(\tilde{X}_j) = 0 \), we have \( \tilde{X}_j = 0 \) almost surely. We then apply Lemma 4 to get,

\[
\|\mathbb{E}(y\tilde{X})\|^2 = \sum_{j=1}^p \mathbb{E}(y\tilde{X}_j)^2 = \sum_{j: \lambda_j > 0} \lambda_j \mathbb{E}(y\tilde{X}_j/\sqrt{\lambda_j})^2 \leq \lambda_1 \sum_{j: \lambda_j > 0} \mathbb{E}(y\tilde{X}_j/\sqrt{\lambda_j})^2 \leq \lambda_1.
\]

Then,

\[
\sum_{i=1}^p |\text{corr}(X_i, y)|^2 = \|\mathbb{E}(yX)\|^2 = \|QQ^T\mathbb{E}(yX)\|^2 = \|Q\mathbb{E}(y\tilde{X})\|^2 \leq \lambda_1,
\]

where we have used the fact that \( Q \) is orthogonal. \( \square \)

### 4.2 Linear regression

We next turn to showing that least squares linear regression solutions cannot have too many large coefficients. Specifically, letting \( \beta = (\beta_1, \ldots, \beta_p)^T \in \mathbb{R}^p \) denote the regression coefficients of least squared error,

\[
\beta = \arg\min_{\alpha=(\alpha_1, \ldots, \alpha_p)^T \in \mathbb{R}^p} \mathbb{E}\left( (\alpha_1 X_1 + \cdots + \alpha_p X_p - y)^2 \right),
\]

we bound the number of \( \beta_i \)'s that can have large magnitude. This is formalized in our next piranha theorem.

**Theorem 5.** Suppose \( X_1, \ldots, X_p, y \) are real-valued random variables with mean zero and unit variance. If \( \beta \in \mathbb{R}^p \) satisfies equation (1), then the squared \( \ell_2 \) norm of \( \beta \) satisfies

\[
\|\beta\|^2 \leq \frac{1}{\lambda_{\min}},
\]

where \( \lambda_{\min} \) is the minimum eigenvalue of the second-moment matrix \( \mathbb{E}(XX^T) \) of \( X = (X_1, \ldots, X_p)^T \).

Consider again the setting where \( X_1, \ldots, X_p \) are independent. In this case, the second-moment matrix \( \mathbb{E}(XX^T) \) will be the identity matrix, and its minimum eigenvalue will be 1. Thus, Theorem 5 states for independent covariates, there may be at most \( 1/\tau^2 \) regression coefficients \( \beta_i \) with magnitude larger than \( \tau \).

**Proof of Theorem 5.** The case where \( \lambda_{\min} = 0 \) is trivial. Thus, assume \( \lambda_{\min} > 0 \). In this case, the second-moment matrix \( \mathbb{E}(XX^T) \) is invertible, its inverse has eigenvalues bounded above by \( 1/\lambda_{\min} \), and

\[
\beta = (\mathbb{E}(XX^T))^{-1}\mathbb{E}(yX).
\]

Define \( \tilde{X} = (\mathbb{E}(XX^T))^{-1/2}X \), so \( \tilde{X} = (\tilde{X}_1, \ldots, \tilde{X}_p)^T \) is a vector of mean-zero and unit-variance random variables with \( \mathbb{E}(\tilde{X}_i\tilde{X}_j) = 0 \) for all \( i \neq j \). By Lemma 4,

\[
\|\mathbb{E}(y\tilde{X})\|^2 = \sum_{j=1}^p \mathbb{E}(y\tilde{X}_j)^2 \leq 1.
\]

Therefore,

\[
\|\beta\|^2 = \|(\mathbb{E}(XX^T))^{-1/2}\mathbb{E}(y\tilde{X})\|^2 = \mathbb{E}(y\tilde{X})^T(\mathbb{E}(XX^T))^{-1}\mathbb{E}(y\tilde{X}) \leq \frac{1}{\lambda_{\min}}\|\mathbb{E}(y\tilde{X})\|^2 \leq \frac{1}{\lambda_{\min}},
\]

where the first inequality uses the upper-bound of \( 1/\lambda_{\min} \) on the eigenvalues of \( (\mathbb{E}(XX^T))^{-1} \). \( \square \)

Theorem 5 implies that we cannot have a regression coefficient bigger than \( 1/\sqrt{\lambda_{\min}} \). If the predictors are standardized and uncorrelated, \( \lambda_{\min} = 1 \). In general \( \lambda_{\min} \) cannot get small without the explanatory variables having sizable correlations with each other.
4.3 Mutual information

Though many statistical analyses hinge on discovering linear relations among variables, not all do. Thus, we turn to a more general form of dependency for random variables, mutual information. Our mutual information piranha theorem will be of a similar form as the previous results, namely that if many covariates share information with a common variable, then they must share information among themselves.

To simplify our analysis, we assume that all the random variables we consider in this section take values in discrete spaces. For two random variables $x$ and $y$, their mutual information is defined as

$$I(x; y) = H(x) - H(x | y) = H(y) - H(y | x),$$

where $H(\cdot)$ and $H(\cdot | \cdot)$ denote entropy and conditional entropy, respectively. These are defined as

$$H(x) = \sum_{x \in \mathcal{X}} p(x) \log \frac{1}{p(x)},$$

$$H(y | x) = \sum_{x \in \mathcal{X}, y \in \mathcal{Y}} p(x, y) \log \frac{p(x)}{p(x, y)},$$

where $\mathcal{X}$ (resp. $\mathcal{Y}$) is the range of $x$ (resp. $y$), $p(x, y)$ is the joint probability mass function of $x$ and $y$, and $p(x)$ is the marginal probability mass function of $x$.

We use the following facts about entropy and conditional entropy.

**Fact** (Chain rule of entropy). For random variables $X_1, \ldots, X_p$,

$$0 \leq H(X_1, \ldots, X_p) = \sum_{i=1}^{p} H(X_i | X_1, \ldots, X_{i-1}).$$

Moreover, for any other random variable $y$,

$$0 \leq H(X_1, \ldots, X_p | y) = \sum_{i=1}^{p} H(X_i | y, X_1, \ldots, X_{i-1}).$$

**Fact** (Conditioning reduces entropy). For random variables $x, y, z$,

$$H(x | y, z) \leq H(x | y) \leq H(x).$$

Using these facts, we can prove the following mutual information piranha theorem.

**Theorem 6.** Given random variables $X_1, \ldots, X_p$ and $y$, we have

$$\sum_{i=1}^{p} I(X_i; y) \leq H(y) + \sum_{i=1}^{p} I(X_i; X_{-i}),$$

where $X_{-i} = (X_1, \ldots, X_{i-1}, X_{i+1}, \ldots, X_p)$.

**Proof.** Using the definition of mutual information, we have

$$H(X_i | X_{-i}) \geq H(X_i) - I(X_i; X_{-i}).$$

Since conditioning reduces entropy, this implies

$$H(X_i | X_1, \ldots, X_{i-1}) \geq H(X_i | X_{-i}) = H(X_i) - I(X_i; X_{-i}).$$

Then, by the chain rule of entropy,

$$H(X_1, \ldots, X_p) = \sum_{i=1}^{p} H(X_i | X_1, \ldots, X_{i-1}) \geq \sum_{i=1}^{p} H(X_i) - I(X_i; X_{-i}). \quad (2)$$

The chain rule of entropy combined with the fact that conditioning reduces entropy implies

$$H(X_1, \ldots, X_p | y) \leq \sum_{i=1}^{p} H(X_i | y) \quad (3)$$

Plugging equations (2) and (3) into our formula for $I(X_1, \ldots, X_p; y)$ gives
\[ I(X_1, \ldots, X_p; y) = H(X_1, \ldots, X_p) - H(X_1, \ldots, X_p | y) \]
\[ \geq \sum_{i=1}^{p} H(X_i) - I(X_i; X_{-i}) - H(X_i | y) \]
\[ = \sum_{i=1}^{p} I(X_i; y) - I(X_i; X_{-i}). \]

Now we can also write,
\[ I(X_1, \ldots, X_p; y) = H(y) - H(y | X_1, \ldots, X_p) \leq H(y). \]

Rearranging yields the theorem.

One corollary of Theorem 6 is that for any random variable \( y \), there can be at most \( p \leq H(y)/\alpha \) random variables \( X_1, \ldots, X_p \) that (a) are mutually independent and (b) satisfy \( I(X_i; y) \geq \alpha \).

## 5 Correlations in a finite sample

We now turn our focus back to correlations, this time in a finite sample. Suppose we conduct a survey with data on \( p \) predictors \( X \) and one outcome of interest \( y \) on a random sample of \( n \) people, and then we evaluate the correlations between the outcome and each of the predictors.

We collect the data in an \( n \times p \) matrix \( X \) with \( n > p \), where each of the columns \( X_1, \ldots, X_p \in \mathbb{R}^n \) of \( X \) has mean zero and unit \( \ell_2 \) norm, and we will use \( \text{corr}(x, y) \) for \( x, y \in \mathbb{R}^n \) (neither in the span of the all-ones vector \( \mathbb{1} \)) to denote the sample correlation:
\[
\text{corr}(x, y) = \frac{\sum_{i=1}^{n} (x_i - \mu_x)(y_i - \mu_y)}{\sqrt{\sum_{i=1}^{n} (x_i - \mu_x)^2 \sum_{i=1}^{n} (y_i - \mu_y)^2}},
\]
where \( \mu_x = \frac{1}{n} \sum_{i=1}^{n} x_i \) and \( \mu_y = \frac{1}{n} \sum_{i=1}^{n} y_i \).

An application of Theorem 3 tells us that any non-constant vector \( y \in \mathbb{R}^n \) satisfies
\[
0 \leq \sum_{j=1}^{p} |\text{corr}(X_j, y)|^2 \leq \sigma_1^2,
\]
where \( \sigma_1 \geq \cdots \geq \sigma_p \geq 0 \) denote the singular values of \( X \). Moreover, it is not hard to see there exists a vector that achieves the upper bound, namely the top singular vector of \( X \).

This analysis shows a worst-case piranha theorem: a bound on the number of large correlations with all possible response vectors. Stronger results can be obtained if we consider average behavior. Here, we consider a stochastic piranha theorem in which we assume that \( y \) is uniformly distributed on the unit sphere in \( \mathbb{R}^n \). Our result will hold for any choice of radially symmetric random vector \( y \) that is independent of \( X \), but we state it for the uniform distribution over the unit sphere for concreteness. We choose a radially symmetric distribution because we have no reason to give preference to one direction over another. Recall the value of studying average as well as worst-case behavior in areas of numerical analysis such as random matrix theory.

The following theorem demonstrates this principle, showing that the maximum sum of squared correlations, an \( O(1) \) quantity in \( n \), is generally much larger than the expected sum of square correlations. Specifically, the following theorem shows that the expected sum of squared correlations decays like \( 1/n \).

**Theorem 7.** Let \( y \) be uniformly distributed on the unit sphere in \( \mathbb{R}^n \). Then
\[
\mathbb{E} \left( \sum_{i=1}^{p} \text{corr}(X_i, y)^2 \right) = \frac{p}{n-1}.
\]
If \( y \) is uniformly distributed on the unit sphere in \( \mathbb{R}^n \), then for large \( n \), the distribution of \( y \) is well approximated by \( (Z_1, \ldots, Z_n) \) the \( n \)-dimensional multivariate Gaussian with mean zero and covariance \( \frac{1}{n} I \). In particular, \( (Z_1, \ldots, Z_n) \) is spherically symmetric, and
\[
\mathbb{E}(Z_1^2 + \cdots + Z_n^2) = 1 \quad \text{and} \quad \text{var}(Z_1^2 + \cdots + Z_n^2) = O(1/n^2).
\]
As a consequence, for large \( n \), the distribution of sum of squared correlations is well approximated by a linear combination of independent \( \chi^2 \) random variables, each with one degree of freedom: 
\[
\frac{1}{n-1} (\lambda_1^2 \xi_1 + \cdots + \lambda_p^2 \xi_p).
\]
Combining this observation with Theorems 3 and 7, for any \( n \times p \) matrix (or sample of data) \( X \), if a vector \( y \) is distributed according to a spherically symmetric distribution, then \( \sum_{i=1}^p \text{corr}(X_i, y)^2 \) is supported on \([0, \sigma^2_1]\), has expectation \( p/(n-1) \), and for large \( n \) has \( O(1/n^2) \) variance.

6 Discussion and directions for future work

The piranha problem is a practical issue: as discussed in the references in Sections 1 and 3, it has interfered with research in fields including social priming, evolutionary psychology, economics, and voting behavior. An understanding of the piranha problem can be a helpful step in recognizing fundamental limitations of research in these fields along with related areas of application such as marketing and policy nudges (Szárszi et al., 2022). We suspect that a naive interpretation of the butterfly effect has led many researchers and policymakers to believe that there can be many large and persistent effects; thus, there is value in exploring the statistical reasons why this is not likely. In this way, the piranha problem resembles certain other statistical phenomena such as regression to the mean and the birthday coincidence problem, in that there is a regularity in the world that surprises people, and this regularity can be understood as a mathematical result. This motivates us to seek theorems that capture some of this regularity in a rigorous way. We are not all the way there, but this seems to us to be a valuable research direction.

6.1 Bridging between deterministic and probabilistic piranha theorems

Are there connections between the worst-case bounds in Section 4, constraints on main effects and interactions (Rogers, 2002), the probabilistic bounds in Section 5, priors for the effective number of nonzero coefficients (Piironen and Vehtari, 2017), and models such as the \( R^2 \) parameterization of linear regression as proposed by Zhang et al. (2020)? We can consider two directions. The first is to consider departures from the parametric models such as the multivariate normal and \( t \) distributions and work out their implications for correlations and regression coefficients. The second idea is to obtain limiting results in high dimensions (that is, large numbers of predictors), by analogy to central limit theorems of random matrices. The idea here would be to consider a \( n \times (p + 1) \) matrix and then pull out one of the columns at random and consider it as the outcome, \( y \), with the other \( p \) columns being the predictors, \( X \).

6.2 Regularization, sparsity, and Bayesian prior distributions

There has been research from many directions on regularization methods that provide soft constraints on models with large numbers of parameters. By “soft constraints,” we mean that the parameters are not literally constrained to fall within any finite range, but the estimates are pulled toward zero and can only take on large values if the data provide strong evidence in that direction.

Examples of regularization in non-Bayesian statistics include wavelet shrinkage, lasso regression, estimates for overparameterized image analysis and deep learning networks, and models that grow in complexity with increasing sample size. In a Bayesian context, regularization can be implemented using weakly informative prior distributions (e.g., Greenland and Mansournia, 2015) or more informative priors that can encode the assumed sparsity (e.g., Carvalho et al., 2010). Classical regularization is motivated by the goal of optimizing long-run frequency performance, and Bayesian priors represent additional information about parameters, coded as probability distributions. The various piranha theorems correspond to different constraints on these priors and thus even weakly informative priors should start by encoding these constraints.

From a different direction is the idea that any given data might allow some only some small number of effects or, more generally, a low-dimensional structure, to be reliably learned. More generally, models such as the horseshoe (Carvalho et al., 2010) assume a distribution of effect sizes with a sharp peak near zero and a long tail, which represent a solution to the piranha problem by allowing a large number of predictors without overflowing variance.
6.3 Nonlinear models

So far we have discussed linear regression, with theorems capturing different aspects of the constraint that the total $R^2$ cannot exceed 1. We can make similar arguments for nonlinear regression.

For example, consider a model of binary data with 20 causal inputs, each of which is supposed to have an independent effect of 0.5 on the logistic scale. Aligning these factors in the same direction would give an effect of 10, enough to change the probability from 0.01 to 0.99, which would be unrealistic in applied fields ranging from marketing to voting where no individual behavior can be predicted to that level of accuracy. One way to avoid these sorts of extreme probabilities would be to suppose the predictors are highly negatively correlated with each other, but in practice, input variables in social science tend to be positively, not negatively correlated (consider, for example, conservative political ideology, Republican party identification, and various issue attitudes that predict Republican vote choice and have positive correlations among the population of voters). The only other alternative that allows one to keep the large number of large effects is for the model to include strong negative interactions, but then the effects of the individual inputs would no longer be stable, and any effect would depend very strongly on the conditions of the experiment in which it is studied. It should be possible to express this reasoning more formally.

6.4 Implications for social science research

Although we cannot directly apply these piranha theorems to data, we see them as providing some relevance to social science reasoning.

As noted at the beginning of this article, there has been a crisis in psychology, economics, and other areas of social science, with prominent findings and apparently strong effects that do not appear in attempted replications by outside research groups; see, for example, Gordon et al. (2020). Discussions of the replication crisis have touched on many aspects of the problem, including estimating its scale and scope, identifying the statistical errors and questionable research practices that have led researchers to systematically overestimate effect sizes and be overconfident in their findings, and studying the incentives of the scientific publication process that can allow entire subfields to get lost in the interpretation of noise.

The research reviewed in the present article is related to, but different from, the cluster of ideas corresponding to multiple comparisons, false discovery rates, and multilevel models. Those theories correspond to statistical inference in the presence of some specified distribution of effects, possibly very few nonzero effects (the needle-in-a-haystack problem) or possibly an entire continuous distribution, but without necessarily any concern about how these effects interact.

The present article goes in a different direction, asking the theoretical question: under what conditions is it possible for many large effects to coexist in a multivariate system? In different ways, our results rule out or make extremely unlikely the possibility of multiple large effects or “piranhas” among a set of random variables. These theoretical findings do not directly call into question any particular claimed effect, but they raise suspicions about a model of social interactions in which many large effects are swimming around, just waiting to be captured by researchers who cast out the net of a quantitative study.

To more directly connect our theorems with social science would require modeling candidate predictor and outcome variables in a subfield, similar to multiverse analysis (Steegen et al., 2016). Any general implications for social science would only become clear after consideration of particular research areas.

A. Gelman. Here are just some of the factors that have been published in the social priming and related literatures as having large effects on behavior, 2023. [https://statmodeling.stat.columbia.edu/2023/11/25/some/](https://statmodeling.stat.columbia.edu/2023/11/25/some/).

A Proof of Theorem 7

For any \( x = (x_1, \ldots, x_n)^T \in \mathbb{R}^n \) such that \( x \neq \lambda I \) for all \( \lambda \in \mathbb{R} \) (i.e., \( x \) is not in the span of \( I \)), we write \( x^* \in \mathbb{R}^n \) to denote the “standardized” vector given by the formula,

\[
x^* = \frac{x - \frac{1}{n}(x^T I) I}{\|x - \frac{1}{n}(x^T I) I\|} = \frac{x - \left(\frac{1}{n} \sum_{j=1}^{n} x_j\right) I}{\sqrt{\sum_{i=1}^{n} (x_i - \frac{1}{n} \sum_{j=1}^{n} x_j)^2}}.
\]

The unit vector \( x^* \) in \( \mathbb{R}^n \) is orthogonal to \( I \). Using this notation, we have

\[
corr(x, y) = (x^*)^T (y^*)
\]

for any \( x, y \in \mathbb{R}^n \) not in the span of \( I \).

Write the singular value decomposition of \( X \) as

\[
X = \sum_{k=1}^{p} \sigma_k U_k V_k^T,
\]

where \( U_1, \ldots, U_p \in \mathbb{R}^n \) are orthonormal left singular vectors of \( X \), \( V_1, \ldots, V_p \in \mathbb{R}^p \) are orthonormal right singular vectors of \( X \), and \( \sigma_1 \geq \cdots \geq \sigma_p \geq 0 \) are the singular values of \( X \).

Recall that we assume \( X_1, \ldots, X_p \) satisfy \( I^T X_i = 0 \) and \( \|X_i\| = 1 \) for all \( i = 1, \ldots, p \). This implies the following lemma.

**Lemma 8.** \( X_i = X_i^* \) for all \( i = 1, \ldots, p \), and \( U_k = U_k^* \) for all \( k = 1, \ldots, p \).

**Proof.** The assumption on \( X_i \) implies that \( X_i^* = X_i \) for each \( i \). Moreover, the assumptions imply that the all-ones vector \( I \) is orthogonal to the range of \( X \), which is spanned by \( U_1, \ldots, U_p \). Hence \( U_k = U_k^* \) for each \( k \) as well.

We then take advantage of the following lemma for expressing the sum of squared correlations.

**Lemma 9.** For any vector \( y \in \mathbb{R}^n \) such that \( y \neq \lambda I \) for all \( \lambda \in \mathbb{R} \),

\[
\sum_{i=1}^{p} \text{corr}(X_i, y)^2 = \sum_{k=1}^{p} \lambda_k^2 (U_k^* y)^2.
\]

**Proof.** By direct computation:

\[
\sum_{i=1}^{p} \text{corr}(X_i, y)^2 = \sum_{i=1}^{p} ((X_i^*)^T (y^*))^2 = \sum_{i=1}^{p} (X_i^* y)^2 = \|X^* y\|^2 = \sum_{k=1}^{p} \lambda_k V_k^T U_k^* y^2 = \sum_{k=1}^{p} \lambda_k^2 (U_k^* y)^2.
\]

**Proof of Theorem 7.** By Lemma 8, the vectors \( U_1, \ldots, U_p \) are orthogonal to the unit vector \( \frac{1}{\sqrt{n}} I \). We extend the collection of orthonormal vectors \( U_1, \ldots, U_p, \frac{1}{\sqrt{n}} I \) with orthonormal unit vectors \( U_{p+1}, \ldots, U_{n-1} \) to obtain an orthonormal basis for \( \mathbb{R}^n \). With probability 1, the random vector \( y \) is not in the span of \( I \). Hence, \( y^* \) is well defined and can be written uniquely as a linear combination of the aforementioned basis vectors:

\[
y^* = a_1 U_1 + \cdots + a_{n-1} U_{n-1} + a_n \frac{1}{\sqrt{n}} I,
\]

where
\[ a_k = \begin{cases} U_k^* y^* & \text{if } 1 \leq k \leq n - 1, \\ 0 & \text{if } k = n \text{ (since } I^T y^* = 0) \end{cases} \]

and

\[ 1 = a_1^2 + \cdots + a_{n-1}^2 \]

(since \( y^* \) is a unit vector). In particular, \( 1 = \mathbb{E}(a_1^2) + \cdots + \mathbb{E}(a_{n-1}^2) \), which by symmetry implies that \( \mathbb{E}(a_k^2) = \frac{1}{n-1} \) for each \( k = 1, \ldots, n - 1 \). Then, by Lemma 9,

\[
\mathbb{E} \left( \sum_{i=1}^{p} \text{corr}(X_i, y)^2 \right) = \mathbb{E} \left( \sum_{k=1}^{p} \lambda_k^2 (U_k^* y^*)^2 \right) = \sum_{k=1}^{p} \lambda_k^2 \mathbb{E}(a_k^2) = \frac{1}{n-1} \sum_{k=1}^{p} \lambda_k^2
\]

Since \( \lambda_i^2 \) are the eigenvalues of \( X^T X \) and the columns of \( X \) have unit \( \ell_2 \) norm,

\[
\frac{1}{n-1} \sum_{k=1}^{p} \lambda_k^2 = \frac{p}{n-1}
\]

because the trace of \( X^T X \) is equal to the sum of its eigenvalues.
